the crack will keep growing until it reaches the next damage zone boundary. however, it will do so at a different velocity. typically, for a steady load case, the crack will grow at a rate governed by the stress intensity at the crack tip. in the damage zone, the crack will have enough space to grow so that the stress intensity is no longer a factor controlling the growth rate. as such, the crack will grow as fast as it can. where n = loading rate in n/m^2 ; a = the initial length of the crack or damage zone in meters; h = damage zone depth in m; t = time in s; v = stress intensity at the crack tip in mpa/m ; and $f(t)$ = load-time history. thus the crack will grow at a

given load rate as $(v_t - v/t) f(t)$. note the stress intensity is a function of time and the crack is tracked at a constant distance. when the crack reaches the end of the damage zone, it will stop growing due to the inability of the material to carry more load. for fatigue crack growth the rhs is no longer zero, since the dynamic load is applied at the crack tip. notice, however, that k_{app}/σ_y is no longer a factor; and that the growth rate is a function of the strain rate. thus it is clear that for the case of fatigue crack growth the growth rate is dependent on the strain rate, material strength (or other control factor), and the maximum stress intensity. for the

strain-controlled case, the growth rate is dependent on the stress intensity at the crack tip, the rate at which the load is applied (in this case the strain rate), and the amount of strain (or damage zone size) within the damage zone. the more strain there is, the faster the crack will grow.

a ductile material will deform before failing, resulting in a rounded crack tip. in contrast, a brittle material will fail in a more brittle manner, resulting in a sharp crack tip. a ductile material will deform elastically while a brittle material will fail elastically, resulting in no plastic deformation. for the current case, the factors of safety are as follows: ss schenectady: stressed crack, unstressed crack ss schenectady: stressed crack, stressed crack ss schenectady: unstressed crack, unstressed crack ss schenectady: unstressed crack, stressed

crack this is the standard approach for evaluating acceptability. however, if the applied stress is deemed unnecessary, it is possible to use the same evaluation methodology but change the residual strength curve. the residual strength curve can be influenced by a combination of additional stress and crack size. the image below shows a chart that illustrates the residual strength curve. the first vertical line represents the critical crack size for a given stress level. the second vertical line represents the critical crack size for the design stress level. the curves that arise from these intersections are referred to as influenced residual

strength curves. the ss schenectady was designed with a near-critical crack size. the maximum design stress was achieved as the ship was assembled. however, upon completion of sea trials, the ship was returned to dock. as the loading increased due to the rough seas, the crack grew, and the ship split in half while sitting at dock. 5ec8ef588b
